### ABSTRACT

Base rock of the Burgaz dam in the eastern part of the city of İzmir consists of micaschists having different physical and mechanical properties due to weathering and fracturing. The first aim is to compute the amount of settlement and ultimate bearing capacity value of micaschist both in and beneath the cutoff zone by using the results of pressuremeter tests. In addition, data from in-situ and some laboratory tests, which were used in the establishment of the relations between elastic modulus of the micaschist rock mass ( $E_M$ ) and uniaxial compressive strength ( $\sigma_c$ ),  $E_M/E_{intact}$  ratios and RQD values. Comparison of in-situ and estimated rock mass deformation moduli by considering the RQD values was also performed. Pressuremeter tests indicate that for a dam with 115 m height and a base width of 58 m, the settlement will vary between 2.13 and 2.26 mm. The second aim of this work is to measure compression and shear wave velocities in order to obtain both the ratio of dynamic elastic modulus to Poisson's ratio  $(E/\nu)_{dynamic}$  and to compare  $(E/\nu)_{dynamic}$  to  $(E/\nu)_{static}$ . Test results reveal a positive linear relation of  $(E/\nu)_{dynamic} = (E/\nu)_{static} \cdot 0.968$ . The sonic wave velocity of the micaschist is highly related to the testing direction. This study not only discusses the relationships between  $E_{static}$  and sonic wave velocity ( $V_p$ ) and  $E_{dynamic}$ , but also the anisotropy effect arisen due to the schistosity planes with different orientations.

**Keywords:** Dam Structure, Micaschist, Pressuremeter Test, Settlement, Rock Material Classification, Anisotropy.

### ÖZ

İzmir'in doğusunda yer alan Burgaz barajının temel kayacını ayırma ve kırılma nedeniyle farklı fiziksel ve mekanik özelliklere sahip mikaşistler oluşturur. Bu çalışmanın birinci amacı, presiyometre deneylerinin sonuçlarını kullanarak hem cutoff zonunda hem de altında yer alan mikaşistlerin nihai taşıma güçlerini ve oturma miktarlarını hesaplamaktır. Buna ek olarak, bazı laboratuvar ve yerinde deneylerden elde edilen veriler, mikaşist kayacın elastisite modülü ( $E_M$ ) ve sağlam kayanın tek eksenli sıkışma dayanımı ( $\sigma_c$ ),  $E_M/E_{intact}$  oranları ve RQD değerleri arasındaki ilişkilerin kurulmasında kullanılmıştır. Mikaşist kayacın kütleliğin yerinde ölçülmüş elastisite modülü değerleriyle, RQD değerlerini dikkate alan tahmin edilmiş elastisite modülü değerleri karşılaştırılmıştır. Presiyometre

deney sonuçları, 58 m taban genişliğine ve 115 m yüksekliğe sahip bir baraj için oluşacak oturmaların 2.13 mm ile 2.26 mm arasında değişeceğine işaret etmektedir. Bu çalışmanın ikinci amacı; ultrasonik dalga hızlarından ( $V_p$  ve  $V_s$ ) yararlanarak dinamik elastisite modülünün ( $E_{dyn}$ ) Poisson oranına ( $\nu$ ) olan oranını,  $(E/\nu)_{dyn}$  belirlemek ve  $(E/\nu)_{dyn}$  ile  $(E/\nu)_{statik}$  oranlarının karşılaştırılmasını yapmaktır. Deney sonuçları pozitif lineer bir ilişki vermiştir;  $(E/\nu)_{dyn} = 0.968 (E/\nu)_{statik}$ . Mikaşistlerin sonik dalga hızının deney yönüyle oldukça ilişkili olduğu belirlenmiştir. Bu çalışma sadece  $E_{statik}$  ve sonik dalga hızı ilişkilerini tartışmaz, farklı konumlara sahip şistozite düzlemleri nedeniyle mikaşistlerde artan anizotropi etkisini de ele alır.

## INTRODUCTION

Burgaz dam is a rock-fill dam constructed on Falaka River about 1 km north of Zeytinova town located in the Bayındır region of İzmir Province (Figure 1). The purpose of the dam is to supply irrigation water for a total land area of 35.68 km<sup>2</sup>. The dam reservoir, which has a height of 115 m from the river bed and the dam body fill volume of 4.25 million m<sup>3</sup>, is purposed to have the water storage capacity of 33 million m<sup>3</sup>. Base rock of the Burgaz dam consists of micaschists. The behaviour of the micaschist rock mass is governed by the deformability of the base rock beneath the dam. The base rock of the dam must resist approximately 2 MPa total stress applied by the weight of dam itself and the strength of the rock must be sufficiently high because heavy pressures on the foundation of the dam will occur. This work gives the information on some physical and mechanical properties of the foundation rock beneath the dam structure, and about the settlement and bearing capacity values of the foundation rock. The design of the dam was based on these tests. Our study including a comprehensive investigation will hence be the first on the micaschists of the Menderes Massive in Turkey from the engineering geological point of view.

The values of elastic modulus ( $E_M$ ) representing the micaschist rock mass were obtained from Menard pressuremeter tests (MPT) and these values were used in settlement and bearing capacity analyses. Comparison of in-situ and estimated rock mass deformation moduli by considering the RQD values is performed in this

study. Comparison of the intact rock parameter such as  $E_i$  with those derived from in-situ tests is important in terms of the determination of relevant parameters for the dam design. Rock mass deformation modulus estimation by correlations considering RQD value has been performed since Coon and Merritt (1970). The correlations have included RQD (Gardner, 1987; Kayabası et al., 2003; Zhang and Einstein, 2004; Kincal and Koca, 2019). The estimated ratios considering the RQD values and in-situ ratios ( $E_{MPT}/E_i$ ) based on the pressuremeter test results ( $E_{MPT}$ ) and laboratory deformability tests are also compared. This comparison will indicate whether the elastic modulus representing the micaschist rock mass, which was used in the settlement analyses, is suitable, or not. On the other hand, the relationship between  $E_M$  and uniaxial compressive strength ( $\sigma_c$ ) values is also investigated for the same purpose mentioned above in this study. Rowe and Armitage (1984) related the rock mass deformation modulus ( $E_M$ ) for weak rocks deduced from a large number of field tests, and it was found as follows;  $E_M = 0.215 \times \sqrt{\sigma_c}$ , where  $\sigma_c$  is in MPa.

Another aim of this work is to obtain some strong correlations among sonic velocity and porosity, UCS and static modulus for the micaschists of the Menderes Massive. Empirical equations were then developed to predict the UCS, dynamic elastic modulus and dynamic Poisson's ratio based on the ultrasonic wave velocities. In order to determine the static modulus of the micaschist rock material, there are two ways proposed in this study; one of these

is to utilize from dynamic elastic modulus ( $E_{\text{dyn}}$ ) and another one is from  $V_p$ . This paper is also intended to establish a relation between static and dynamic elastic moduli of the micaschist rock material as well as the relationship between static modulus ( $E_{\text{static}}$ ) and  $V_p$ . The relationships between static and dynamic moduli and P-wave velocity were investigated by various authors in related literature (Eissa and Kazi, 1988; Heap et al., 2014; Najibi et al., 2015; Brotons et al., 2014; 2016).

UCS tests were performed with strain gauges and the values of static elasticity modulus ( $E_{\text{static}}$ ) and Poisson's ratio were determined from the stress-strain curves. Thus, empirical equations were also obtained between the UCS values and  $E_{\text{static}}$  and  $(E/\nu)_{\text{static}}$  and  $(E/\nu)_{\text{static}}$  and  $(E/\nu)_{\text{dynamic}}$ . These relationships mentioned above have been presented in the literature since Deere and Miller, 1966; Lama and Vutukuri, 1978; Al-Shayea, 2004; Uslu, 2017; Kadakçı Koca and Koca, 2018). Such correlations may provide a good estimation in some related engineering works. Correlations between sonic velocity, UCS and other physical properties and static modulus are important in terms of providing correct information for future exploration in the same or close areas, since a number of dams are planned to be built on the same schistous units belonging to the Menderes Massive in Aegean region by the General Directorate of State Hydraulic Works.

A comprehensive understanding of the anisotropy effect is necessary for a reliable design of engineering project such as dam construction (Behrestaghi et al., 1996; Singh et al., 2001; Nasserli et al., 2003). For this reason, P-wave velocity ( $V_p$ ) measurements and compression tests were performed on the core specimens with different schistosity plane orientations. A review of the aforementioned work indicates that the maximum failure strength is either at  $\alpha = 0^\circ$  or  $\alpha = 90^\circ$  and the minimum value usually is around

$\alpha = 30^\circ$ . The shape of the curve between UCS ( $\sigma_c$ ) and  $\alpha$  - angle reflects the anisotropy effect on the rock. In this work, loading was vertically applied on the core specimens with different schistosity plane orientations ( $\alpha = 0 - 3^\circ$ ,  $\alpha = 28^\circ - 30^\circ$ , and  $\alpha = 90^\circ$ ). In addition, the relationship between UCS and sonic wave velocity was investigated previously in the literature for various rock types (Mc Cann et al., 1990 in Entwisle et al., 2005; Gupta and Seshagiri Rao, 1998; Sharma and Singh 2008; Andrade and Saraiva 2010). In this paper, a large number of ultrasonic pulse velocity tests were conducted on the micaschist intact core specimens obtained from ASK-1 borehole drilled in the Burgaz dam site.

## GEOLOGY OF BURGAZ DAM SITE

Metamorphic rocks located in and nearby the Burgaz dam site have a simple tectonostratigraphy that consists of Paleozoic cover series and Pre-Cambrian core series which tectonically overlaid the cover series (Figure 1). Core series consist of homogenous garnet micaschists. Mineral composition of the garnet micaschist can be given as garnet-biotite-muscovite-plagioclase-quartz with accessory minerals of rutile, apatite and zircon. This rock contains 40% feldspar, 30% quartz, 20% mica (biotite+muscovite), 4 - 5% garnet and 1 - 2% other constituents. They display well developed lepidoblastic texture (Figure 2). The light brown color and weak schistosity are macroscopically characteristic features to recognize the schists at the Burgaz dam site.

Core samples obtained from the ASK-1 borehole have been examined petrographically. In the schist specimens, the interlocking fabric is created by the parallel to the sub-parallel arrangement of large platy minerals such as feldspar, mica, and quartz (Figure 2). In particular, strongly weathered schists tend to split into planes due to parallel orientation of

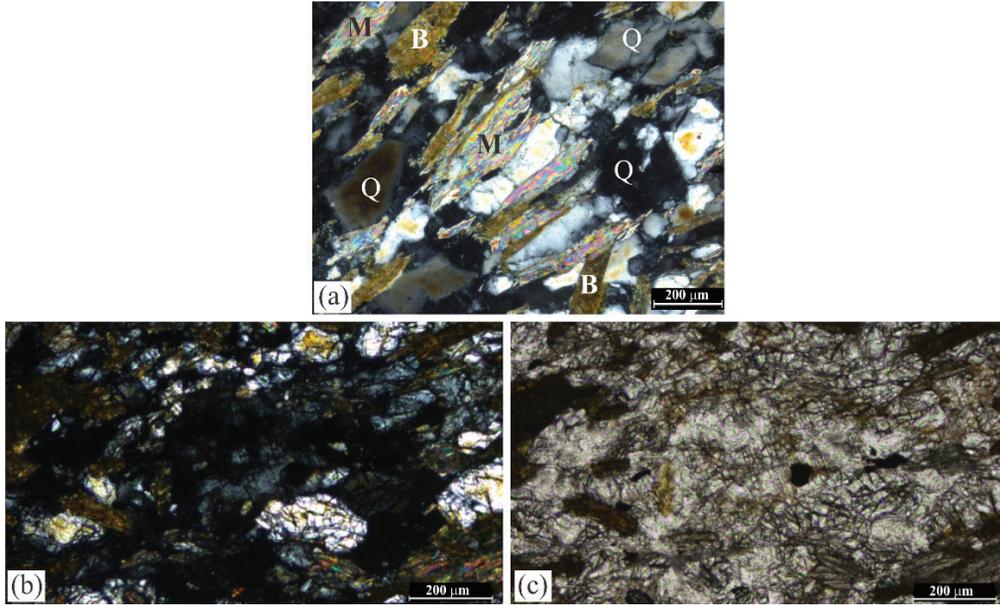

Figure 2. A view from the thin section of garnet micaschist (a) Q: quartz, M: muscovite, B: biotite, (Sample no: 1), (b) parallel nicol view, (c) cross nicol view.

## METHODS

The design of the dam was based on the results of pressuremeter tests. Design parameters such as limit pressure ( $P_L$ ) and rock mass modulus ( $E_M$ ) were evaluated using pressuremeter test results which can be used for the design of shallow and deep foundations in a fractured rock mass (Hughes, 2002; Tarnawski, 2004; Işık et al. 2008). 21 Menard pressuremeter tests were undertaken not only to assess bearing capacity and possible settlement at the base of the dam but also determine the depth of the cutoff level. Initially, the pressure applied was equivalent to 1 Atmosphere, increasing by 3 Atmospheres for each 2 m depth interval. The test results were evaluated for the rockfill dam with 115 m height and a base width of 58 m.

Both  $V_p$  and  $V_s$  measurements were performed using Proceq Pundit Lab device.  $V_p$

and  $V_s$  are the functions of elastic properties and rock density. Measurements therefore, provide the computing elastic modulus ( $E_{dyn}$ ) and Poisson's ratio ( $\nu$ ). These parameters are as follows;

$$E_{dyn} = \frac{\bar{n} \times (3V_p^2 - 4V_s^2)}{\left(\frac{V_p^2}{V_s^2}\right) - 1}, \quad \nu_{dyn} = \frac{\left(\frac{V_p^2}{2V_s^2}\right) - 1}{\left(\frac{V_p^2}{V_s^2}\right) - 1}, \quad \text{where } \rho$$

is density of rock material.

Thus, the ratio of  $E_{dyn}$  to  $\nu_{dyn}$  was computed for nine intact core specimens. In the present investigation, the ratios of  $(E/\nu)_{dynamic}$  obtained from the measurements of sonic wave velocities were compared with the ratios of  $(E/\nu)_{static}$  obtained from the direct static method. Sonic wave velocities of the micaschists were obtained by application of ultrasonic compression and shear waves pulses to the core specimen in accordance with ASTM test designation D 2845-08 (ASTM, 1990). Measurements were taken

along the axis of the core specimens and sonic wave velocities were determined from 50 core specimens. By considering the sonic velocity test on the rock specimens, the values of  $V_p$  and  $V_s$  of the core specimens under both dry and water saturated conditions were calculated. The velocities were measured on the core specimens with differently oriented schistosity planes of the rock such as parallel, inclined ( $28^\circ - 30^\circ$ ) and vertical to the schistosity planes. On the other hand, the values of  $E_t$  (tangent elastic modulus) and Poisson's ratio ( $\nu$ ) were calculated at 50% of the UCS from the stress versus strain curve of the rock. The values of UCS of the micaschist specimens were determined directly by testing 54 mm diameter NX size core specimens with a 1:2 dimensional ratio. The specimen was loaded until failure and stress-strain curve was recorded. Loadings were vertically applied to the schistosity planes (ASTM, 1992).

UCS tests were performed on that of 50 from 51 core specimens since the core specimen 47 was revoked due to the pre-existed joint. However, the deformability tests were solely performed on just 9 out of 50 intact core specimens. Furthermore, nine core specimens were taken from the core boxes to perform UCS tests under saturated conditions. The aim was to determine the strength reduction in saturated core specimens in proportion to the dry core specimens. In these tests, schistosity plane orientations were not considered. On the other hand, medium grained, slightly weathered blocks were extracted from the micaschist rock mass at the right bank of the dam reservoir to investigate the anisotropy effect. They were trimmed with their sides perpendicular to each other to facilitate coring at different inclinations, using a special frame fitted to the base of the laboratory drilling machine. Twenty-four specimens at different

schistosity plane orientation angles ( $\alpha = 0-3^\circ$ ,  $28^\circ - 30^\circ$  and  $90^\circ$ ) were cored from the three rock blocks. Thus, all laboratory tests were conducted on a total of 80 core specimens.

### Engineering Geological Conditions of the Dam Site

ASK-1 drill-hole log contains some geological descriptions such as core recovery (CR%), RQD%, joint frequency ( $\lambda$ ), and Lugeon test results (Figures 3 and 4). It is seen that the permeable and highly permeable levels have developed parallel to the schistosity planes with a nearly horizontal orientation ( $\alpha < 10^\circ$ ), (Figure 3). The values of RQD along the borehole between 40 and 41.50 m, 51 and 52 m, 59 m and 63 m were determined to be less than 25% (Figure 5). These zones are of the property of very poor quality rock and permeable. Analysis of drilling data shows that permeability increases with poor – very poor rock quality.

Micaschists with poor quality were intersected between 31.5 m and 37.5 m, 39.5 m, 40 m – 41.5 m, 51 m – 52 m and 59 m – 63 m (Figure 4). The zones below 40 m depth were named as fractured zones in this work. Although a joint set was developed, permeability values under the cutoff level (21.0 - 28.5 m) were determined as  $1.69 \times 10^{-5}$  and  $3.23 \times 10^{-5}$  cm/s and the mean value was also computed as  $2.02 \times 10^{-5}$  cm/s (low permeable) due to its direction. While the test results of permeability are in interval between  $3.23 \times 10^{-4}$  cm/s and  $1.69 \times 10^{-5}$  cm/s near the foundation of the dam, under the depth of 60 m the test results are found to be an interval between  $1.3 \times 10^{-5}$  cm/s and  $6.5 \times 10^{-5}$  cm/s. This case indicates that the values of permeability decrease with the depth (Figure 3).

The maximum thickness of the alluvium in the river bed is 21.0 m (Figure 3). The cut off zone begins at the base of the alluvium (Figure 3). This zone is underlain by the moderately (WM) and highly weathered (WH) micaschists with quartzite lenses. Core advance into the WM

and WH micaschist level is 53.5 m long (31.5–85 m). Intact rock cores were recovered from this zone. Some physical and mechanical properties of 50 micaschist core specimens are presented in Table 1.

$\sigma_c$  values of the 39 core specimens (78% of all core specimens) recovered from depths between 40-47 and 63-67 m, and 73-85 m were examined under two groups; i)  $\sigma_c > 50$  MPa,  $2000 < V_p < 4000$  m/s (26% of all core specimens), ii)  $15 < \sigma_c < 50$  MPa,  $2000 < V_p < 4000$  m/s (52% of all core specimens), (Table 2 and Figure 5).

Table 2. The degree of weathering and corresponding ultrasonic velocities for the micaschists from the Burgaz Dam site.

Çizelge 2. Burgaz Baraj sahasındaki mikaşistlerin ayrışma dereceleri ve onlara karşılık gelen ultrasonik ses dalgası hızları.

Weathering state	Number of intact core specimens	UCS (MPa)	Ultrasonic velocity (m/s)		$\alpha$ -ratio $\left( \frac{V_{p \text{ saturated}}}{V_{p \text{ dry}}} \right)$ “For all data”
			Dry (average)	Saturated (average)	
WS	6 (12%)	$\sigma_c > 50$	4236.0	5097.6	1.210
WM	13 (12%)	$\sigma_c > 50$	3576.7	4374.8	1.223
WH	26 (52%)	$15 < \sigma_c < 50$	2498.8	3109.0	1.289
WC	5 (10%)	$15 < \sigma_c < 50$	1830.8	2450.0	1.338

Explanation: WS: Slightly weathered, WM: Moderately weathered, WH: Highly weathered, WC: Completely weathered.

While the micaschist core specimens including the first group (WH – WM) were classified as “moderately weathered, strong rock”, those included in the second group were classified as “slightly weathered (WS), moderately strong rock” (Figure 5). On the other hand, values of the five core specimens (10% of all core specimens) recovered from depths between 28.5 and 37 m were found to be in the range between 20 MPa and 30 MPa (Figure 5). In addition,  $V_{p \text{ dry}}$  values of these core specimens (WC) were determined to be less than 2000 m/s. These core specimens were classified as “completely weathered, moderately strong rock” (Table 2 and Figure 5).

### Anisotropic Behaviour of the Micaschists

$V_p$  and UCS tests were conducted on the core specimens as shown in Figure 6.  $V_p$ -values were measured on the core specimens with differently oriented schistosity planes such as parallel ( $\alpha = 0 - 3^\circ$ ) to the schistosity planes, inclined ( $28^\circ - 30^\circ$ ) to the schistosity planes, and vertical ( $\alpha = 90^\circ$ ) to the schistosity planes, under dry and saturated conditions, respectively (Figure. 6). After the processes mentioned above, the  $(V_{p \text{ sat}} / V_{p \text{ dry}})$  ratios were computed for the core specimens and shown in Table 3.

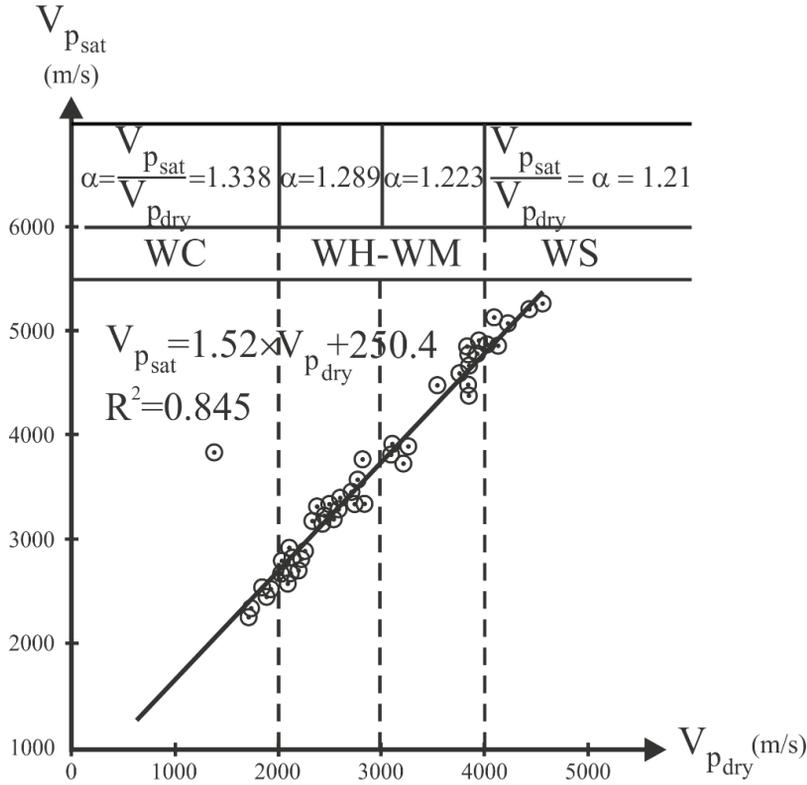

Figure 5. Relationships between ultrasonic wave velocities under dry and water saturated conditions and the values of  $\alpha$ -ratio ( $V_{psat}/V_{pdry}$ ).

Şekil 5. Kuru ve suya doymuş şartlarda ultrasonik ses dalgası hızlarıyla  $\alpha$ -oranı ( $V_{psat}/V_{pdry}$ ) değerleri arasındaki ilişkiler.

$V_p$ -values obtained parallel or nearly parallel to the schistosity planes ( $\alpha = 0 - 3^\circ$ ) were the highest as compared to other orientations in both dry and water saturated conditions.  $V_p$ -values acquired at  $28^\circ - 30^\circ$  were higher than those vertical to the schistosity planes ( $\alpha = 90^\circ$ ) in dry condition, while in water saturated condition,  $V_p$  values were obtained as close to each other for both  $\alpha = 28^\circ - 30^\circ$  and ( $\alpha = 90^\circ$ ), (Table 3). P-wave velocities obtained for  $\alpha = 28^\circ - 30^\circ$  are higher than those obtained for  $\alpha = 90^\circ$  in dry condition. On the other hand, in saturated condition, the mean values of P-wave velocities for anisotropy angles both  $\alpha = 28^\circ - 30^\circ$  and

$\alpha = 90^\circ$  are nearly obtained in the same level. As a result, it is determined that the  $V_p$  value decreases as  $\alpha$ -angle increases. On the other hand, as the  $\alpha$ -angle decreases, the ( $V_{psat}/V_{pdry}$ ) ratio increases. A similar trend was observed for quartz mica schists by Zhang et al. (2011). The difference between the mean values of the wave-velocities measured under saturated and dry conditions ( $V_{psat}/V_{pdry}$ ) and the percent of increasing the velocity were determined for the various  $\alpha$ -angles (Table 3). It is determined that as  $\alpha$ -angle increases, the difference between  $V_{psat}$  and  $V_{pdry}$  also increases.

	N: 8				
	( $V_{psat}$ ) ( $V_{pdry}$ )	1770 (134%)			

N: number of test,  $\alpha$ -angle: Anisotropy angle (It is defined as an angle between the applied compressive loading and the schistosity plane orientation).

It was determined that the ratio is the largest (2.34) for  $\alpha = 90^\circ$  and the smallest (1.21) for  $\alpha = 0-3^\circ$  in this study. When P–wave propagates along the schistosity plane ( $\alpha=0-3^\circ$ ), the presence of water makes a slight influence on the wave velocity ( $V_{psat}/V_{pdry} = 1.21$ ). On the other hand, when P–wave propagating at the vertical position

to the schistosity planes ( $\alpha = 90^\circ$ ), the presence of water significantly increased the wave velocities ( $V_{psat}/V_{pdry} = 2.34$ ). UCS test results of the mica schist core specimens with differently oriented schistosity planes in both dry and water saturated conditions are presented in Table 4.

\*N: Number of test

In both dry and saturated conditions, the highest UCS values were obtained from the uniaxial compression tests when loading is perpendicular to the schistosity planes ( $\alpha = 90^\circ$ ). On the other hand, the smallest ones were obtained from the tests when loading is inclined to the schistosity planes ( $\alpha = 28-30^\circ$ ). The relationships between the  $\sigma_{\text{cdry}}/\sigma_{\text{csat}}$  ratio and  $\alpha$  - angle were examined in detail (Figure 7). The largest and smallest  $\sigma_{\text{cdry}}/\sigma_{\text{csat}}$  ratios are found as 2.35 ( $\alpha = 28^\circ-30^\circ$ ) and 1.37 ( $\alpha = 90^\circ$ ), respectively. For this reason, the curve acquired from the variation of  $\sigma_{\text{cdry}}/\sigma_{\text{csat}}$  ratio with  $\alpha$ -angle displays a reverse V - shape ( $\Lambda$  - shape). Variation of the UCS – mean values with  $\alpha$ -angle in both dry and saturated conditions was also examined to better characterize the anisotropy effect of the mica schists (Figure 8). The curves obtained from the variation of the UCS - mean values with  $\alpha$  - angle display V - shape (Figure 8). Besides, the V-shape may result from only three conditions for the plane direction being considered. The anisotropy behavior of micaschists is clearly shown in UCS test results, i. e. the ratio of  $\sigma_{\text{cdry}}/\sigma_{\text{csat}}$  varies with the  $\alpha$  - angle between the applied compressive loading and the schistosity plane orientation. In dry condition, while the UCS – mean value was found as 74.3 MPa when loading during the compression tests was perpendicular to the schistosity planes ( $\alpha = 90^\circ$ ), it was found as 39.0 MPa when loading was inclined to the schistosity planes ( $\alpha = 28^\circ- 30^\circ$ ). In saturated condition, these values were found as 54.1 MPa and 16.6 MPa, respectively (Figure 8).

While in the relationship between  $\alpha$ -angle and  $V_p$ , the values of  $V_p$  in saturated condition were obtained higher than those in the dry condition. In the relationship between  $\alpha$ -angle and UCS-values, UCS-values were obtained as higher than those in water saturated condition (Figure 8). While the V-shape from the relationship between  $\alpha$ -angle and UCS was

acquired, the relationship between  $\alpha$ -angle and the curve of  $V_p$  did not display such a trend (Figure 8). As expected, they do not agree with each other.

### Determination of the Deformability and Modulus Ratios of the Micaschists

In order to determine the modulus ratios, nine deformability tests were performed on the intact core specimens (Figure 9). While the UCS values were determined in a range between 29.8 MPa and 71.6 MPa, the values of  $E_t$  were also determined in a range between 5.98 GPa and 36.4 GPa (Table 5). This large variability can be attributed to various weathering grades, not to rock anisotropy, because loadings in all tests were vertically applied on the schistosity planes. Deformability is classified into five categories as proposed by the IAEG (Anon, 1979). According to this classification, high deformability is less than  $15 \times 10^3$  MPa, low deformability is greater than  $30 \times 10^3$  MPa. Except for the core specimens number 7, 16 and 21, micaschists were classified as moderate deformable ( $15.52 \times 10^3$  MPa  $\leq E_t \leq 27.12 \times 10^3$  MPa). The values of of the core specimens number 7, 16 and 21 were found as 5.98, 10.82 and 13.0 GPa, respectively (Figure 9). They were classified as “high deformable rock”. The elastic modulus value of the core specimen number 46 was determined as a low deformable category ( $E_t > 30 \times 10^3$  MPa), (Table 5). The ultimate deformation (strain at failure) is considerably high in weathered micaschist which appears as an outcome of a more ductile behaviour of the material. The higher values of  $\sigma_c$ , the slope of the ascending branch of the stress–strain diagram, in comparison with the slope exhibited by weathered mica schists (Figure 9). Their results with the modulus ratios are given in Table 5.

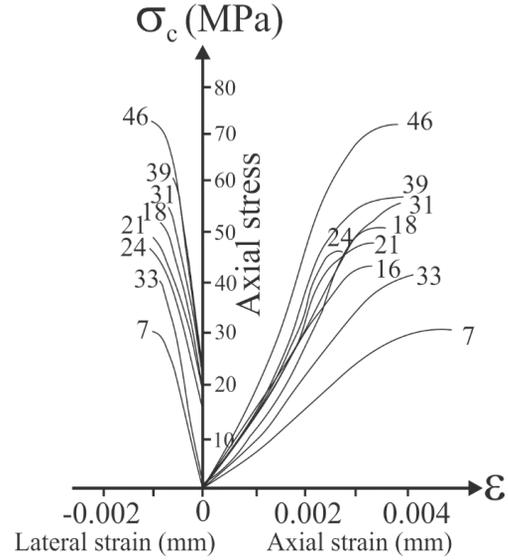

Figure 9. The axial and diametric stress-strain curves of the micaschists.

Şekil 9. Mikaşistlerin aksenal ve çapsal gerilme-deformasyon eğrileri.

According to the engineering classification of intact rocks suggested by Deere and Miller (1966), except the core specimen 7, micaschists were classified as “average modulus ratio” and “moderately strong rocks”. The specimen number 7 was classified as “average modulus ratio” and “weak rock”. According to the proposed method by Türk and Dearman (1983), micaschists were classified as “moderately deformable and moderately strong and strong rocks” (Figure 10). The specimens 7 and 46 were classified as “moderately strong and very deformable” and “strong and slightly deformable rock”, respectively (Figure 10). In this work, the values of  $\sigma_c$  and  $E_t/\nu$  were determined in the ranges between 29.8 MPa and 71.6 MPa, and 34.76 and 145.6 GPa, respectively.

Table 5. Deformability test results and modulus ratios for the micaschist core specimens.

Çizelge 5. Mikaşist karot örnekleri için deformabilite deney sonuçları ve modül oranları.

Sample no	n%	$\sigma_c$ (MPa)	$\nu$	$E_t$ (GPa)	$E_t/\sigma_c$	$E_t\nu$ (GPa)
7	7.75	29.8	0.17	5.98	201	34.76
16	1.92	42.6	0.26	10.82	254	41.61
18	2.01	51.4	0.22	17.86	374	81.20
21	1.97	48.0	0.17	13.00	271	76.47

33	4.20	40.5	0.20	15.52	383	77.60
39	1.44	56.2	0.30	27.12	482	90.40
46	1.74	71.6	0.25	36.40	508	145.6
X $\pm$ S.D	2.75 $\pm$ 2.03	48.89 $\pm$ 11.74	0.22 $\pm$ 0.04	18.47 $\pm$ 9.04	363.96 $\pm$ 107.2	81.06 $\pm$ 32.8

From the graph presented in Figure 10, it is seen that the UCS values increase as the ratios of ( $\frac{E_t}{\nu}$ ) increase. UCS test results, the values of  $E_t$  and  $\nu$ , modulus ratios ( $\frac{E_t}{\sigma_c}$ ) and the value of ( $\frac{E_t}{\nu}$ ) for each test are given in Table 5. While the value of modulus ratio of ( $\frac{E_t}{\sigma_c}$ ) was found to be in a range between 200.6 and 508.3, the ratio of ( $\frac{E_t}{\nu}$ ) was found to be in a range between 34.76 GPa and 145.6 GPa with a mean value of 81.06  $\pm$  32.8 GPa (Table 5). Logarithmic, power and linear regression analysis between  $\sigma_c$  and values for the micaschists were performed and  $\frac{E_t}{\nu}$  the Equations 1, 2 and 3 were obtained.

$$\log \sigma_c = \log 5.3936 + m \times \log \left( \frac{E_t}{\nu} \right) \quad (1)$$

Where “m” is slope of the plot.

Power and linear regression analyses between ( $\frac{E_t}{\nu}$ ) and values for the micaschists with medium elastic modulus ratio were performed and then Equations 2 and 3 were obtained. If the correlation coefficients obtained from both analyses are considered, it is seen that the coefficient acquired from the power regression analysis is less than that of the linear regression analysis.

$$\sigma_c = 5.3936 \times \left( \frac{E_t}{\nu} \right)^{0.5047} \quad R^2 = 0.81 \quad (2)$$

$$\sigma_c = 0.3331 \left( \frac{E_t}{\nu} \right) + 21.899, \quad R^2 = 0.86 \quad (3)$$

Comparison of the test results from the Burgaz dam site with those from Selçuk-İzmir (Elçi, 2003) was also performed in this study. For this, test results on WS-micaschists from Selçuk-İzmir and WM-WH micaschists from the Burgaz dam site-İzmir were plotted all together in Figure 10. When weathering grade increases, both strength and ( $E_t/\nu$ ) values decrease along a straight line which is represented by the equation in Figure 10. While the slope of the line given in Equation 4 is 0.3331, in Equation 5, it is 0.1779. The slope of line decreased nearly two times (Figure 10). However, micaschist test results follow a power law;

$$\sigma_c = 7.5393 \times \left( \frac{E_t}{\nu} \right)^{0.4244} \quad R^2 = 0.89 \quad (4)$$

$$\sigma_c = 0.1779 \left( \frac{E_t}{\nu} \right) + 33.691 \quad R^2 = 0.84 \quad (5)$$

According to the Equations 4 and 5, WM and WS micaschists with medium elastic modulus ratio gave reasonably acceptable power and linear relations, respectively.

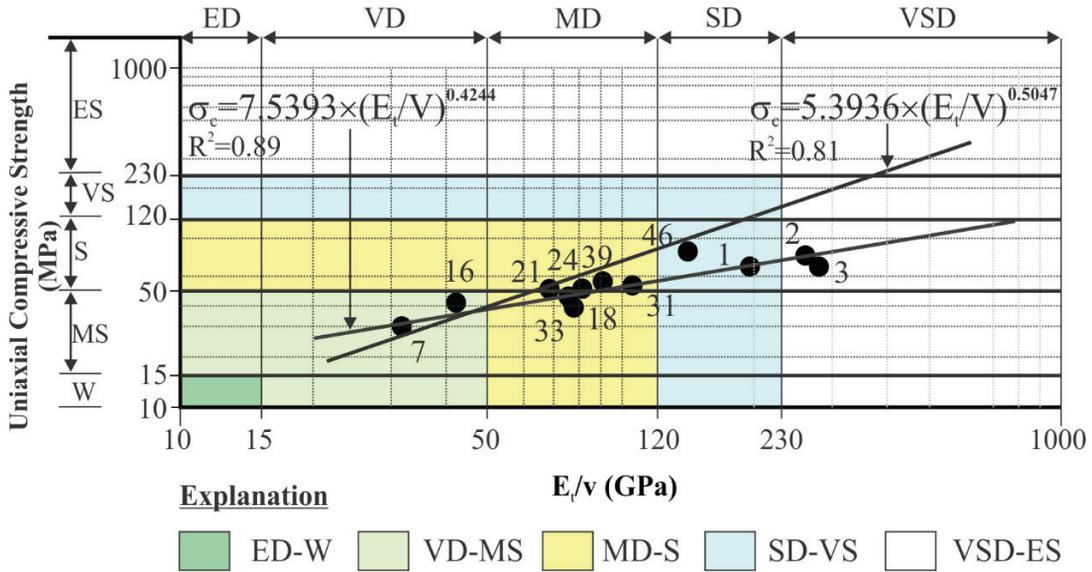

Figure 10. Graphical presentation of the relationship between  $(\frac{E_t}{v})$  ratio and uniaxial compressive strength (7, 18, 24, 31, 33 and 39: from the Burgaz dam site, 1, 2, and 3: Selçuk-İzmir,  $n\% \leq 1.6$ ,  $\sigma_c \geq 76$  MPa, = 50 - 70 GPa). Engineering classification of intact micaschist core specimens (W: Weak, MS: Moderately strong, S: Strong, VS: Very strong, ES: Extremely strong, ED: Extremely deformable, VD: Very deformable, MD: Moderately deformable, SD: Slightly deformable, VSD: Very slightly deformable).

Şekil 10.  $(\frac{E_t}{v})$  oranıyla tek eksenli basınç dayanımı ilişkisinin grafiksel sunumu (7, 18, 24, 31, 33 ve 39: Burgaz barajı sahasından, 1, 2, ve 3: Selçuk-İzmir'den,  $n\% \leq 1.6$ ,  $\sigma_c \geq 76$  MPa, = 50 - 70 GPa). Taze mikaşist karot numunelerinin mühendislik sınıflaması (W: Wayıf, MS: Orta dayanımlı, S: Dayanımlı, VS: Yüksek dayanımlı, ES : Çok yüksek dayanımlı, ED: Aşırı derecede deforme olabilen, VD: Çok deforme olabilen, MD: Orta derecede deforme olabilen, SD: Az deforme olabilen, VSD: Çok az deforme olabilen).

**Relation Between  $(\frac{E}{v})_{dynamic}$  and  $(\frac{E_t}{v})_{static}$  for the Micaschists**

$V_p$  and  $V_s$  velocities were measured to determine the ratio of  $(E/v)_{dyn}$  for nine intact core specimens. Results of the measurements  $(E/v)_{dyn}$  and  $v$  are presented in Table 7. The ratios of  $(E_t/v)_{static}$  for the same core specimens are also presented in this table. The results show that  $(E/v)_{dyn}$  is greater than  $(E_t/v)_{static}$  (Table 6). The graph of  $(E/v)_{dyn}$  versus  $(E_t/v)_{static}$  is drawn on a log-log paper (Figure 11) and the relation given in Equation 6 was obtained;

$$(\frac{E}{v})_{dyn} = 1.2707 (\frac{E_t}{v})_{static}^{0.968} \quad R^2 = 0.96, n = 9 \quad (6)$$

The plot of test results indicates that there are two points to consider; a) When  $(E_t/v)_{static}$  is high, as for the moderately strong micaschists,  $(E/v)_{dyn}$  is also high and values are greater than  $(E_t/v)_{static}$ . b) The decrease in  $(E_t/v)_{static}$  value shows a corresponding decrease in  $(E/v)_{dyn}$ . The values of  $E_t$  and  $v$  from the laboratory tests performed under dynamic and static conditions were found to be different from one another. For this reason, both the values of  $E_t$  and  $v$  were considered in which the relations were examined. Figure 11 shows the log-log scale plot of “Average Modulus Ratio” and  $(E/v)_{dyn}$  against  $(E_t/v)_{static}$  for the weathered micaschists from the Burgaz dam

site. It is interesting to note that the test results of the micaschists gave a power relation of  $y=ax^b$  [ $(\frac{E}{\nu})_{dyn} = 1.2707 \times (\frac{E}{\nu})^{0.968}$ ,  $R^2= 0.96$ ], as a linear relation: [ $(\frac{E}{\nu})_{dyn} = 79.192 \ln (\frac{E}{\nu})_{static} - 252.14$  on a log-log scale,  $R^2= 0.88$ ].

Relationships between the static and dynamic moduli and  $V_p$  were also investigated in this study. As known, the dynamic modulus ( $E_{dyn}$ ) is generally higher than the static, but there are instances where the opposite is true. The higher the  $E_p$ , the greater the agreement between the static and dynamic values is (Eissa and Kazi, 1988). The relationships between the static and dynamic moduli for different types of rocks and ranges of values proposed by various authors (Brotons et al. 2016; Christaras et al. 1994; Eissa

and Kazai, 1998) are summarized in Table 7. In addition, various correlations between  $E_{static}$  and  $E_{dyn}$  moduli were proposed by various authors (Figure 12). They have been obtained from rocks whose dynamic modulus varied between 5 and 130 GPa, and including rocks of igneous, sedimentary and metamorphic origins (all rock types). k-ratio ( $E_{dyn} / E_{static}$ ) has been used in their works by several authors (Al-Shayea, 2004; Martinez et al., 2012; Brotons et al., 2014; 2016) as well as the current study. In Figure 12 the line of slope 1:1 from the origin, represents the points where  $k=1$ , so that the values of  $k>1$  are located to the right of that line (Figure 12). All of the curves in Figure 12 are located in the right of the diagonal line, indicating  $k>1$  values.

Table 7. Relationships between  $E_{static}$  and  $E_{dynamic}$  moduli proposed by various authors.Çizelge 7. Farklı yazarlar tarafından önerilen  $E_{static}$  ve  $E_{dynamic}$  modülleri arasındaki ilişkiler.

Reference	Relationship	R <sup>2</sup>	E <sub>dyn</sub> (GPa)	Rock type
Eissa and Kazi (1988)	$E_{static} = 0.74 \times E_{dyn} - 0.82$	0.70	5 – 130	All types
Christaras et al. (1994)	$E_{static} = 1.05 \times E_{dyn} - 3.16$	0.99	25 – 110	All types
Brotos et al. (2016)	$E_{static} = 11.531 \times \rho_{bulk}^{-0.457} \times E_{dyn}^{1.251}$	0.99	5 – 80	All types
The current study	$E_{static} = 0.8764 \times E_{dyn} - 0.58$	0.97	5 – 30	Mica schist

The evolution of the k-parameter with the modulus for each curve can be seen in Figure 12. The k-values obtained in this study vary from 1.06 to 1.45. The mean value is found as  $1.198 \pm 0.126$ . The values obtained by the other authors are between 0.85 and 1.86 (King, 1983; Vanheerden, 1987; Eissa and Kazi, 1988). The k-values obtained in this study generally agree with the findings of the other authors.

The parameter required in the equations ( $V_p$ ) is easily obtained. It simplifies simplifies the testing necessary for obtaining the static modulus-a dependent variable in all cases. Some equations obtained for the metamorphic rocks were not considered in this study such as the work of King (1983) due to being the values of dynamic elastic modulus in a range from 40 GPa to 120 GPa. They have very high elastic

Figure 11. The plot of  $(\frac{E}{v})_{dynamic}$  against  $(\frac{E}{v})_{static}$  for the micaschists core specimens from the Burgaz dam site.Şekil 11. Burgaz Baraj alanındaki mikaşist karot numuneleri için hazırlanmış olan  $(\frac{E}{v})_{dynamic}$  karşı  $(\frac{E}{v})_{static}$  ilişkisi.

modulus with respect to the micaschists. When considering  $V_p$ ,  $E_{static}$  modulus is calculated with the help of the equations given in Table 8. These equations use  $V_p$  parameter, which hence allows the  $E_{sta}$  modulus of rocks to be estimated quickly and reliably. Excellent matching is observed in Figure 13 for the curves of Brotons et al. (2016) and the current study, and reasonable good matching for the curve of limestone of Najibi et al. (2015).

Two multiple non-linear regression analyses (Milton et al., 1997) were conducted by SPSS software in order to estimate  $E_{static}$  with regard to  $V_p$  and porosity ( $n\%$ ). Two expressions from the analyses are as follows; Model 1:  $E_{static} = V_p^{2.523} \times n^{0.095}$ ,  $R^2 = 0.93$ , RMSE [(Root mean square error). Root mean squared error (RMSE) is the most commonly used error metric. It expresses the square root of the average squared errors of a predictive model. The model is assumed to be as excellent while RMSE is 0]: 0.149 GPa, VAF (Variance accounted for): 92.67. Model 2:  $E_{static} =$

$8.966 V_p \times n^{-0.753}$ ,  $R^2 = 0.75$ , RMSE: 1.80 GPa and VAF: 75.54. As a result, multiple non-linear regression model 1 estimated the  $E_{static}$  values more precisely than other models as having low RMSE (0.149) and high VAF (92.67) values.

### Estimation of Settlement Potential and Bearing Capacity Value

Pressuremeter tests were performed along the ASK-1 borehole profile to determine the values of elastic modulus of micaschists rock masses with various weathering grades. Thus, the amount of settlement and bearing capacity value of micaschists both in and beneath the cutoff zone were calculated by using the values of elastic modulus of the rock masses. The weathering degree of micaschist is varying from moderately weathered to completely weathered and the rock mass is highly jointed (Figure 4 and Table 9). Pressuremeter tests were generally performed in every two meters in ASK 1 borehole between the depth 5.0 m and 53.5 m.

G<sub>M</sub>: Shear modulus [E<sub>M</sub>/2× (1+ ν)]. Settlement we calculated according to the equation suggested by Menard et al. (1962) in this work.

Moderately weathered and fractured micaschists take place under both the zone of pressure bulb and the more fractured zone along the profile of ASK–1 borehole. The first part with 3 m depth of the zone 1 is the zone of bearing

capacity and this zone is important in term of a foundation.

Clarke (1995) indicated that as the ratio of Menard deformation modulus to Menard limit pressure ( $E_M/P_L$ ) is between 10 and 20, the

soil is firm and very firm. This ratio is changing from 5.0 to 20.66 in eight pressuremeter tests performed in ASK 1 borehole between the depths 5.0 m and 28.5 m. It was determined that the thickness of the cutoff zone under the alluvium changes between 5 and 7.5 m on the basis of the core description and the results of pressuremeter tests. These results fundamentally indicate that this zone is a transition zone from hard soil to weak rock. Thirteen pressuremeter tests between the depths 30.5 m and 53.5 m were carried out and yielded Menard deformation modulus were calculated to be between 454.4 MPa and 2150 MPa with an arithmetic mean value of 1479.8 MPa and a standard deviation of 500.1 MPa. It was determined that the  $(E_M/P_L)$  ratio for moderately weathered and fractured micaschists varied from 142.9 to 180.67. By ignoring extremely high and low values, the range of  $(E_M/P_L)$  ratio varies between 154.4 to 179.4 which is still high. As a result, the ratio of  $(E_M/P_L)$  is quite useful and typical values are 9.96 to 20.66 in very decomposed micaschist to the extent of very dense sand (Table 9). This is a transition zone between hard soil and weak rock. On the other hand, the  $(E_M/P_L)$  ratio under the cutoff level (Zone I) reaches up to 142.9 to 180.67 in moderately and highly weathered, and fractured micaschists (Table 9). The aperture of fractures in the rock mass for zone 1 is changing between 1 mm and 1.5 mm and schistosity planes are nearly horizontal. In this case, variations of  $(E_M/P_L)$  ratios are not due to the closing of apertures during pressuremeter tests. Işık et al. (2008) observed that testing depth and disturbance affect the calculated values of the deformation modulus of greywackes. In addition, they remarked that the volume subjected to the applied pressure is small when compared to the rock mass volume. Thus, the deformation modulus of the rock mass derived from the test

should be used cautiously. The effect of variable stress condition in highly fractured mica schist zone (39.5 m – 41.5 m) and testing depth were not considered in this study. Pressuremeter tests indicated that for a 115 m high dam, the settlement would vary between some 2.16 mm and 2.23 mm. The ultimate bearing capacity ( $q_{ult}$ ) at the base of the dam structure was computed as ranging between 2.96 MPa and 3.71 MPa (For the zone 1: -min: 7.90 MPa and -max: 9.95 MPa, coefficient of bearing capacity,  $k$ : 1.1, unit weight: 26.5 kN/m<sup>3</sup>, factor of safety: 3). Bearing capacity analyses were performed according to the equation suggested by Baguelin et al. (1978). After the excavation of cutoff with 7.5 m depth from alluvium at the base of river valley was performed, the dam construction was started. Weathered micaschist unit lies down at this elevation (28 m). The harmonic mean of elastic moduli for three measurements in the micaschist rock mass beneath the dam was computed as 1398.6 MPa (Table 9). Considering the harmonic mean value ( $E_M$ : 1398.6 MPa), the amount of settlement was obtained as 2.16 mm. On the other hand, if the minimum value of elastic modulus of the rock mass for a measurement ( $E_M$ : 1220 MPa) beneath the dam is considered, amount of settlement is calculated as 2.23 mm.

### Relationship Between Elastic Modulus of the Micaschist Rock Mass ( $E_M$ ) and Uniaxial Compressive Strength of the Micaschist Rock Material ( $\sigma_c$ )

Data from in-situ and laboratory tests, which was used in the establishment of the relation between  $E_M$  and  $\sigma_c$ , is presented in Table 10. Variation of the elastic modulus of  $E_M$  with  $\sigma_c$  is investigated (Figure 14). The relations given in Equations 7 and 8 are obtained by using linear and power regression analyses;

$$E_M = 0.322 \sqrt{\sigma_c} - 0.606, R^2 = 0.95 \quad (7)$$

$$E_M = 0.1194 (\sigma_c)^{1.3472}, R^2 = 0.94 \quad (8)$$

36.40	71.6	8.46	2.150	1.820	14.32

The graph showing the variation of the elastic modulus of the micaschist rock mass with  $\sigma_c$  is presented in Figure 14. In this graph, two lines from the current study and Rowe and Armitage (1984) are compared with each other. For the low values of  $\sigma_c$  ( $\sigma_c \geq 32$  MPa), the values of elastic modulus from both equations are quite close to each other. For the high values of  $\sigma_c$ , both trend lines are, however, getting distant from each other.

### Comparison of In-situ and Estimated Rock Mass Deformation Moduli by Considering the RQD-Values

Coon and Merrit (1970) proposed the following equation considering the RQD values;  $\frac{E_M}{E_i} = (0.0231 \times \text{RQD}) - 1.32$ , based on the more data and more recently Zhang and Einstein (2004) recommended the following relations considering the RQD values;

$$\frac{E_M}{E_i} = 0.2 \times 10^{(0.0186 \times \text{RQD} - 1.91)} \text{ (Lower bound),}$$

$$\frac{E_M}{E_i} = 1.8 \times 10^{(0.0186 \times \text{RQD} - 1.91)} \text{ (Upper bound),}$$

$\frac{E_M}{E_i} = 10^{(0.0186 \times \text{RQD} - 1.91)}$ ,  $R^2 = 0.76$  (Mean), where  $E_M$  and  $E_i$  are the deformation modulus of the rock mass and intact rock, respectively.

Pressuremeter test results ( $E_M$ ) performed beneath the cutoff zone (under 30.5 m) were considered in this work. Three pressuremeter tests between the depths 30.5 and 33.5 m were performed and yielded  $E_M$ -values between 1.22 GPa and 1.7 GPa with arithmetic mean value of 1.49 GPa. On the other hand, by ignoring extremely high and low values, the RQD-values in this zone generally vary between 35% and 60% with arithmetic mean value of 48.5% (Figure 4). For the RQD values of 35% and 60%,  $\frac{E_M}{E_i}$  ratios are found as 0.011 (Lower bound) and 0.289

(Upper bound), respectively. The mean value (RQD: 48.5%) is found as 0.0982. At depths between 30.5 m and 33.5 m (bearing capacity zone), the values of static modulus,  $E_t$  vary between 5.98 GPa and 17.86 GPa with arithmetic mean value of 11.55 GPa (Table 5).

$$\text{Lower bound; } \frac{E_M}{E_i(\text{min})} = 0.011, \frac{E_M}{5.98} = 0.011; \\ E_M = 5.98 \times 0.011 = 0.0658 \text{ GPa (65.8 MPa),}$$

$$\text{Upper bound; } \frac{E_M}{E_i(\text{max})} = 0.289, \frac{E_M}{17.86} = 0.289; E_M = \\ 17.86 \times 0.289 = 5.16 \text{ GPa (5160 MPa),}$$

$$\text{Mean; } \frac{E_M}{E_i(\text{mean})} = 0.0982, \frac{E_M}{11.55} = 0.0982; E_M = \\ 11.55 \times 0.0982 = 1.134 \text{ GPa (1134 MPa).}$$

When the RQD-values are considered, it is understood that the lower and the upper bound values of elastic modulus of weathered micaschist rock mass vary between 65.8 MPa and 5160 MPa with arithmetic mean value of 1134 MPa. These values mentioned above are the estimated values obtained from the equations of Zhang and Einstein (2004). On the other hand, the mean ratio based on the pressuremeter test results ( $E_M$ ) and laboratory deformability tests ( $E_i$ ) [ $E_{i(\text{mean})} = \frac{(5.98+10.82+17.86)}{3} = 11.553$  GPa (from Table 5)] for the bearing capacity zone is as follows; Mean:  $\frac{E_{M(\text{mean})}}{E_{i(\text{mean})}} = \frac{1490}{11553} = 0.129$ . This ratio (0.129) takes part between two ratios obtained using the equations of the mean and the upper bound of Zhang and Einstein (2004). For this reason, disturbance during the drilling operations may cause the deformation modulus ( $E_M$ ) obtained from Menard pressuremeter test to become lower than the actual in-situ value. When the estimated ratios considering the RQD-values and in-situ ratios based on the pressuremeter test results ( $E_M$ ) and laboratory deformability tests are compared, it is seen that they are consistent with each other.

## DISCUSSION

The discussions are based on the laboratory tests employed on the intact micaschist core specimens and pressuremeter tests.  $V_s$  as a percentage of  $V_p$  was calculated for the micaschists, and the results are consistent in that average  $V_s$  values are roughly 60% of  $V_p$  values (min: 57.8%, max: 64.2%, mean 61.2% for the mean porosity value of 3.55%). It was determined that the relationships between and UCS, and porosity had a good correlation with the correlation factors  $r = 0.81$  and  $r = 0.88$ , respectively. The porosity and UCS and,  $V_{p-dry}$  and  $V_{p-sat}$ , the UCS and  $V_{p-dry}$  had even better correlations of  $\geq 0.90$ . Empirical relationships proposed in the related literature for the parameters studied were also considered, between  $V_p$  and UCS (Table 11). The proposed equation in this work was in this work is similar to the equation proposed by the equation proposed by Andrade and Saraiva (2010).

It was determined that the micaschists located at the depth between 28.5 and 40 m had lower UCS values when compared with those of under 40 m depth (In this zone, the existence of the micaschist level with the properties of  $V_{p-dry} < 2000$  m/s and  $20.3 < \sigma_c < 28.2$  MPa were determined). This case indicated that a more weathered and fractured material exists in these depths. The depth between 28.5 m and 40 m below the dam should be considered in terms of the compaction grouting. Considering the

results of the deformability tests, the micaschists were classified as “average modulus ratio and moderately strong rock” according to the classification suggested by Deere and Miller (1966). According to the method suggested by Türk and Dearman (1983), they were also classified as “moderately deformable and strong rock”. It was understood that the rock material classification of the micaschists proposed by Türk and Dearman (1983) is similar to Deeres', the difference being in the division of the elastic modulus by Poisson's ratio.

The micaschists take place beneath the cutoff level of the dam were classified as “moderate deformable rock” ( $15 \times 10^3 < E_t < 30 \times 10^3$  MPa). The values of UCS of nine intact core specimens on which deformability tests were performed, were determined to be in the range between 29.8 MPa and 71.6 MPa. The mean value of UCS of all core specimens was also determined as  $48.89 \pm 11.74$  MPa. The values of  $V_{p-dry}$  of the nine core specimens were found to be in the range between 1906 m/s and 3850 m/s. According to the information given above, except core specimen number 7, the eight core specimens were chosen from moderately weathered and “moderately strong” and “strong” micaschist core specimens that represent 78% of all core specimens. The core specimen number 7 was chosen from highly weathered and weak rock micaschist core specimens that represent 10% of all specimens.

$E_M$  values representing the micaschist rock mass were obtained from MPT. These values were used in settlement and bearing capacity analyses. In addition, the excavation depth of cutoff was determined by considering the pressuremeter test results ( $E_M \leq 103.3$  MPa). It was determined that the excavation depth under alluvium changes as a range between 5 m and 7.5 m. It was also determined that the values of  $E_M$  under the cutoff zone are greater than 454.4 MPa. In addition, minimum, maximum and arithmetic mean values of  $E_M$  were determined as 454.4 MPa, 2150 MPa and 1479.8 MPa, respectively. The rock mass modulus obtained from the Rock Mass Rating (RMR) tends to overestimate when compared with  $E_M$  based on MPT (Birid, 2015). Analyses indicated that the settlement for a 115 m high rockfill dam would be in the order of 2.16 mm and 2.23 mm. On the other hand, the ultimate bearing capacity of the micaschist beneath the dam were also computed as ranging between 2.96 MPa and 3.71 MPa.

The relationship between  $\sigma_c$  and  $\frac{E_t}{\nu}$  for the Burgaz's micaschists was determined to be as follows;  $\sigma_c = 5.3936 \times \left(\frac{E_t}{\nu}\right)^{0.5047}$ . As known, weathering decreases not only strength but also the ratio of elastic modulus to Poisson's ratio. The experimental results from the micaschist weathered to different grades (*i.* Burgaz dam site, İzmir *ii.* Selçuk, Belevi, İzmir) were similarly plotted on a log-log paper. Thus, the relationship between  $\sigma_c$  and  $\frac{E_t}{\nu}$  for both Burgaz and Selçuk's micaschists was also determined as follows;  $\sigma_c = 7.5393 \times \left(\frac{E_t}{\nu}\right)^{0.4244}$ . The slope of the strength versus  $\left(\frac{E_t}{\nu}\right)$  plot for a particular rock is constant so that for each rock there is a unique linear equation on a log-log scale.

The plot of  $\left(\frac{E}{\nu}\right)_{dynamic}$  against  $\left(\frac{E_t}{\nu}\right)_{static}$  for the micaschists core specimens (WM) from the Burgaz dam site was obtained. Test results gave

a positive power relation of  $\left(\frac{E}{\nu}\right)_{dynamic} = 1.2707 \left(\frac{E_t}{\nu}\right)_{static}^{0.968}$ ,  $R^2 = 0.96$ . Thus, it will be possible that the ratio of  $\left(\frac{E_t}{\nu}\right)_{static}$  for the micaschists in the Burgaz dam site is computed by measurements of sonic wave velocities on the intact core specimens in the laboratory. In addition, it was understood that  $\left(\frac{E}{\nu}\right)_{dynamic}$  is slightly higher than  $\left(\frac{E_t}{\nu}\right)_{static}$ . This difference can be explained as the presence of fractures as well as weak schistosity planes in micaschists.

Strength reductions in dry and water saturated conditions arisen due to the anisotropy effect were found as 47.5% and 69.3% respectively. These ratios were determined as 55.1% and 75.5% by Zhang et al. (2011). The results obtained from the two works are slightly different from each other. The first reason for this may be mineralogical composition and grain size of minerals. While the ratio of mica minerals changes between 27.9 % and 48.7 % in the study published by Zhang et al. (2011), this ratio is less than 20 % in this work. As compared on the basis of mineralogical compositions, it is seen that the ratios of mica minerals are fairly different from each other. This case negatively affects the strength of the rock. In addition, high mica content in rock can be increased the anisotropy effect. Because mica flakes existing along the schistosity planes easily weather to clay minerals. This is anyway the cause of the relatively weak nature of the schistosity planes. Thus, the sliding movement along these surfaces gets easy. The second reason may be the differences in weathering grade determination of the test specimens employed to the laboratory tests. As known, the investigation of the anisotropy effect must be conducted on the core specimens with the same weathering grade.

Increasing in  $V_p$  for different  $\alpha$  - angles obtained from the measurements taken in dry and water saturated conditions were determined as follows; for  $\alpha = 0 - 3^\circ$ : 17.4%, for  $\alpha = 28^\circ - 30^\circ$ : 36.3% and for  $\alpha = 90^\circ$ : 57.3%. When P - wave propagated vertical to the schistosity planes ( $\alpha = 90^\circ$ ), the presence of water significantly increased the velocity (increasing the velocity: 57.3%). For the P - wave propagated along the schistosity planes ( $\alpha = 0 - 3^\circ$ ), the presence of water only occurred a light effect on the wave velocity (increasing the velocity: 17.4%). In a similar way,  $V_{psat}/V_{pdry}$  ratios were also computed for different orientation of the schistosity planes varying from  $0^\circ$  to  $90^\circ$  with respect to the loading direction. It was determined that the  $V_{psat}/V_{pdry}$  ratio was the highest for  $\alpha = 90^\circ$  (2.34) and the smallest for  $\alpha = 0^\circ - 3^\circ$  (1.21), while the ratio for  $\alpha = 28^\circ - 30^\circ$  was intermediate (1.57). The results obtained from the computations of the  $V_{psat}/V_{pdry}$  ratio and increasing the velocity for different  $\alpha$  - angles agree with each other.

## CONCLUSIONS

It was determined that as the degree of weathering of the micaschists increases, to ratio also increases. On the other hand,  $V_{psat}$  to  $V_{pdry}$  ratio is roughly 1.67. The proposed equation to estimate the UCS values based on the  $V_p$  values is different from the empirical equations in the related literature due to the differences relating to the mineralogy and texture of the rock materials. In order to determine the static modulus of the micaschist rock material, there are two ways proposed in this study; one of these is to utilize from  $E_{dyn}$  and another one is from  $V_p$ . The equations in relation to the static modulus were determined as follows;

$$\begin{aligned} E_{static} &= 0.8767 \times E_{dyn}^{-0.58}, E_{static} = 1.1015 \times V_p^{2.4757}, \\ E_{static} &= V_p^{2.523} \times n^{0.095} \end{aligned} \quad (9)$$

It is concluded that the static modulus can be obtained from the dynamic tests, as shown in the equations for the studies range (i. e.  $E_{dyn}$  values lower than 30.5 GPa and soft rocks). Variation of the elastic modulus of the micaschist rock mass ( $E_M$ ) with UCS-values was investigated and the relation given below was obtained;  $E_M = 0.3221 \sqrt{\sigma_c} - 0.606$ ,  $R^2 = 0.95$ . In this work, the estimated ratios considering the RQD values (the equation of Zhang and Einstein, 2004 was used) and  $(\frac{EMPT}{E_t})$  ratios from this study were compared with each other. As a result, it was determined that they are quite consistent with each other. This case indicates that the elastic modulus representing the micaschist rock mass, which was used in the settlement analyses, is more suitable. It was concluded that the settlement for a 115 m high rockfill dam would be in the order of 2.23 mm. In addition, the ultimate bearing capacities of the micaschists beneath the dam were also computed as ranging between 2.96 and 3.71 MPa. It can be said that this would be a good site for the dam construction in terms of bearing capacity, amount of settlement and the deformability of the base rock beneath the dam structure.

Anisotropy effect will not occur in the bedrock beneath the cutoff level of the dam structure due to the existence of the schistosity planes with nearly horizontal position ( $\alpha < 20^\circ$ ). It was determined that the  $V_p$  - values obtained as parallel to the schistosity planes were greater than those of other orientations in both dry and water saturated conditions. In water saturated condition,  $V_p$ -values were obtained as close to each other for  $\alpha = 28^\circ - 30^\circ$  and  $\alpha = 90^\circ$ . In dry condition,  $V_p$ -values obtained at  $\alpha = 28^\circ - 30^\circ$  were determined to be greater than those normal to the schistosity planes. On the other hand, It was also determined that the presence of water significantly increased the velocity (the velocity increase: 134%) when P-wave propagated as

vertical to the schistosity planes. For the P-wave propagating along the schistosity planes, it was determined that the presence of water slightly affects on the wave velocity (the velocity increase: 21.2 %). It was also determined that the highest UCS – values obtained from the UCS tests when loading is perpendicular to the schistosity planes in dry and water saturated conditions. On the other hand, the lowest ones were obtained from the tests when loading was inclined to the schistosity planes ( $\alpha = 28^\circ - 30^\circ$ ) in similar conditions. It was determined that while the curves of stress values versus anisotropy angle ( $\alpha$ ) displayed a similar “V - shape”, the curves of  $V_p$  did not display such a trend. It was also determined that the largest and smallest  $\frac{\sigma_c^d}{\sigma_c^e}$  ratios were found as 2.35 (for  $\alpha = 28^\circ - 30^\circ$ ) and 1.37 ( $\alpha = 90^\circ$ ), respectively. On the other hand, the maximum strength reductions for dry and water saturated conditions due to the anisotropy effect were computed as 47.51 % and 69.31 %, respectively.

The equation given below was obtained for the micaschist weathered to different grades;  $\sigma_c = 7.5393 \times \left(\frac{E_t}{v}\right)^{0.4244}$ , where “m” is 0.4244. The slope of line (m) for the micaschists is constant and has the characteristic of the rock. On the other hand, the relation of  $\left(\frac{E}{v}\right)_{\text{dyn}}$  versus  $\left(\frac{E_t}{v}\right)_{\text{static}}$  for the weathered schists was found as  $\left(\frac{E}{v}\right)_{\text{static}} = 1.2707 \left(\frac{E_t}{v}\right)^{0.968}$ .
